# Fundamental problems in Distributed Computing

- Efficient distribution of work
  - combating *serialization*
  - Serialization is when work happens serially rather than in parallel
- Consensus
  - combating *failure*

# Grid Computing

# scalability

/ˌskeɪləˈbɪlɪtɪ/

noun

1. the ability of something, esp a computer system, to adapt to increased demands

Collins English Dictionary - Complete & Unabridged 2012 Digital Edition

© Paul Fremantle 2015. This work is licensed under a Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International License  
See <http://creativecommons.org/licenses/by-nc-sa/4.0/>

# Speedup

- The **speedup** is defined as the performance of new / performance of old
  - e.g. move from 1 -> 2 servers
  - New system is 1.8 x faster than the old
    - In terms of transactions/sec (throughput)
  - Speedup = 1.8

# What inhibits speedup?

- In general you can split work into
  - Parallelizable and
  - Serial
  - parts
- The serial parts stop you from scaling

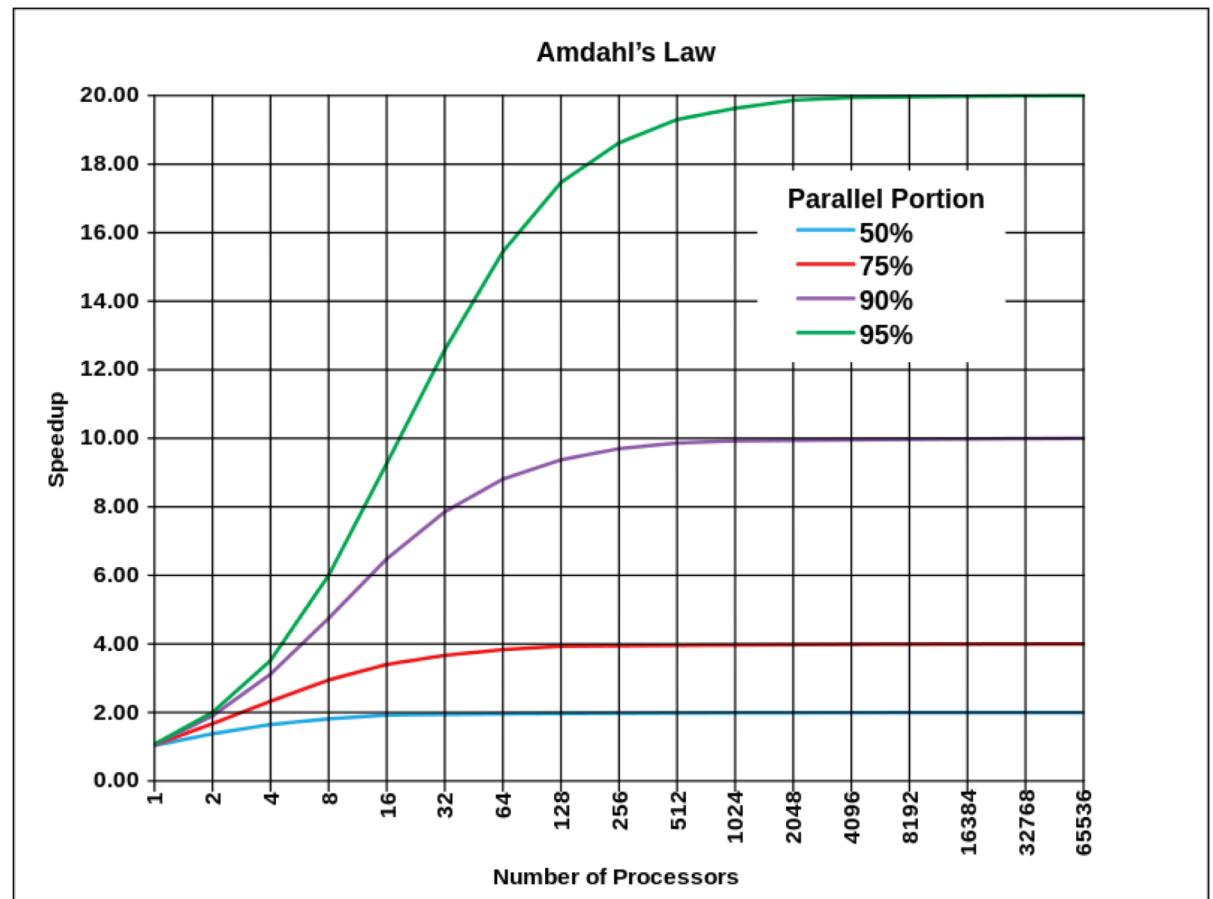

© Paul Fremantle 2015. This work is licensed under a Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International License  
See <http://creativecommons.org/licenses/by-nc-sa/4.0/>

# Amdahl's Law

Theoretical speedup given a fixed data size

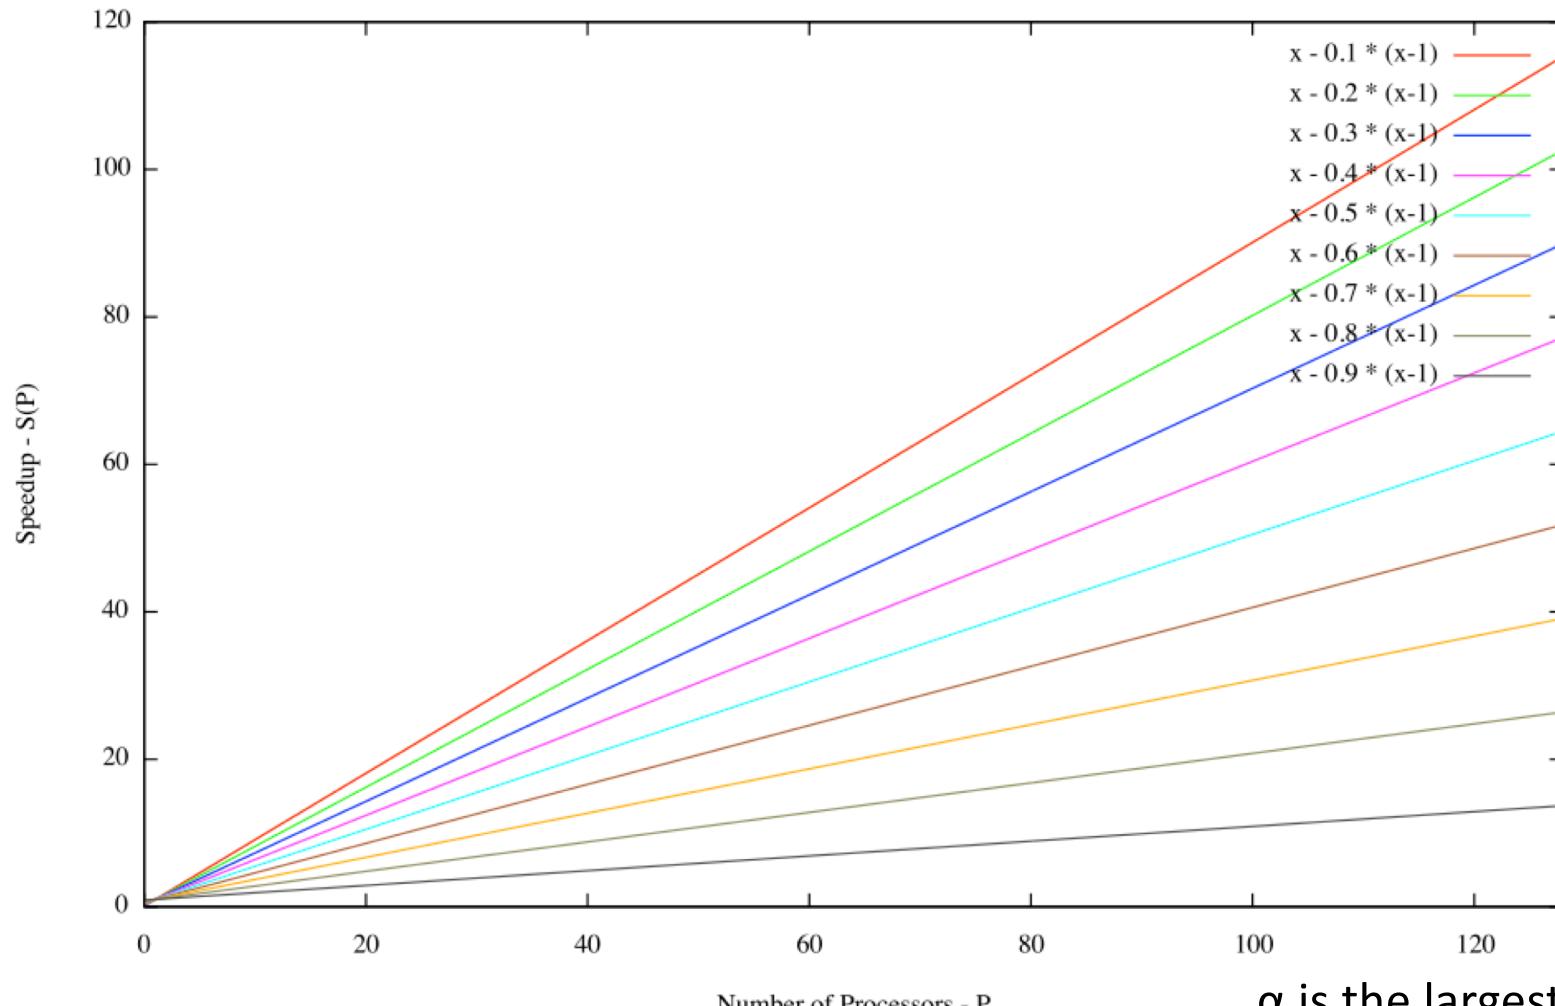

The speedup of a program using multiple processors in parallel computing is limited by the time needed for the serial fraction of the program, given a fixed size of data

# Gustafson's Law

What if the data increases too?

$$S(P) = P - \alpha \cdot (P - 1)$$

$\alpha$  is the largest  
non-parallelizable fraction

# A driving metaphor

- **Amdahl's Law**
  - You are travelling to London (60 miles)
  - 30 miles in you have spent one hour
  - You can never average  $> 60$  mph
- **Gustafson's Law**
  - You are travelling across the US
  - You've spent an hour at 30 mph
  - You can achieve any average speed given enough time and distance

# Karp-Flatt Metric

e is the Karp-Flatt Metric

$\psi$  is the speedup

p is the number of processors

$$e = \frac{\frac{1}{\psi} - \frac{1}{p}}{1 - \frac{1}{p}}$$

e = 0 is the best

e = 1 indicates no speedup

e > 1 indicates adding processors  
slows down the system!!!

# Karp-Flatt Metric Example

$$e = \frac{\frac{1}{\psi} - \frac{1}{p}}{1 - \frac{1}{p}}$$

$$\begin{aligned}\psi &= 2 \\ p &= 2 \\ e &= 0\end{aligned}$$

$e = 0$  is the best

$e = 1$  indicates no speedup

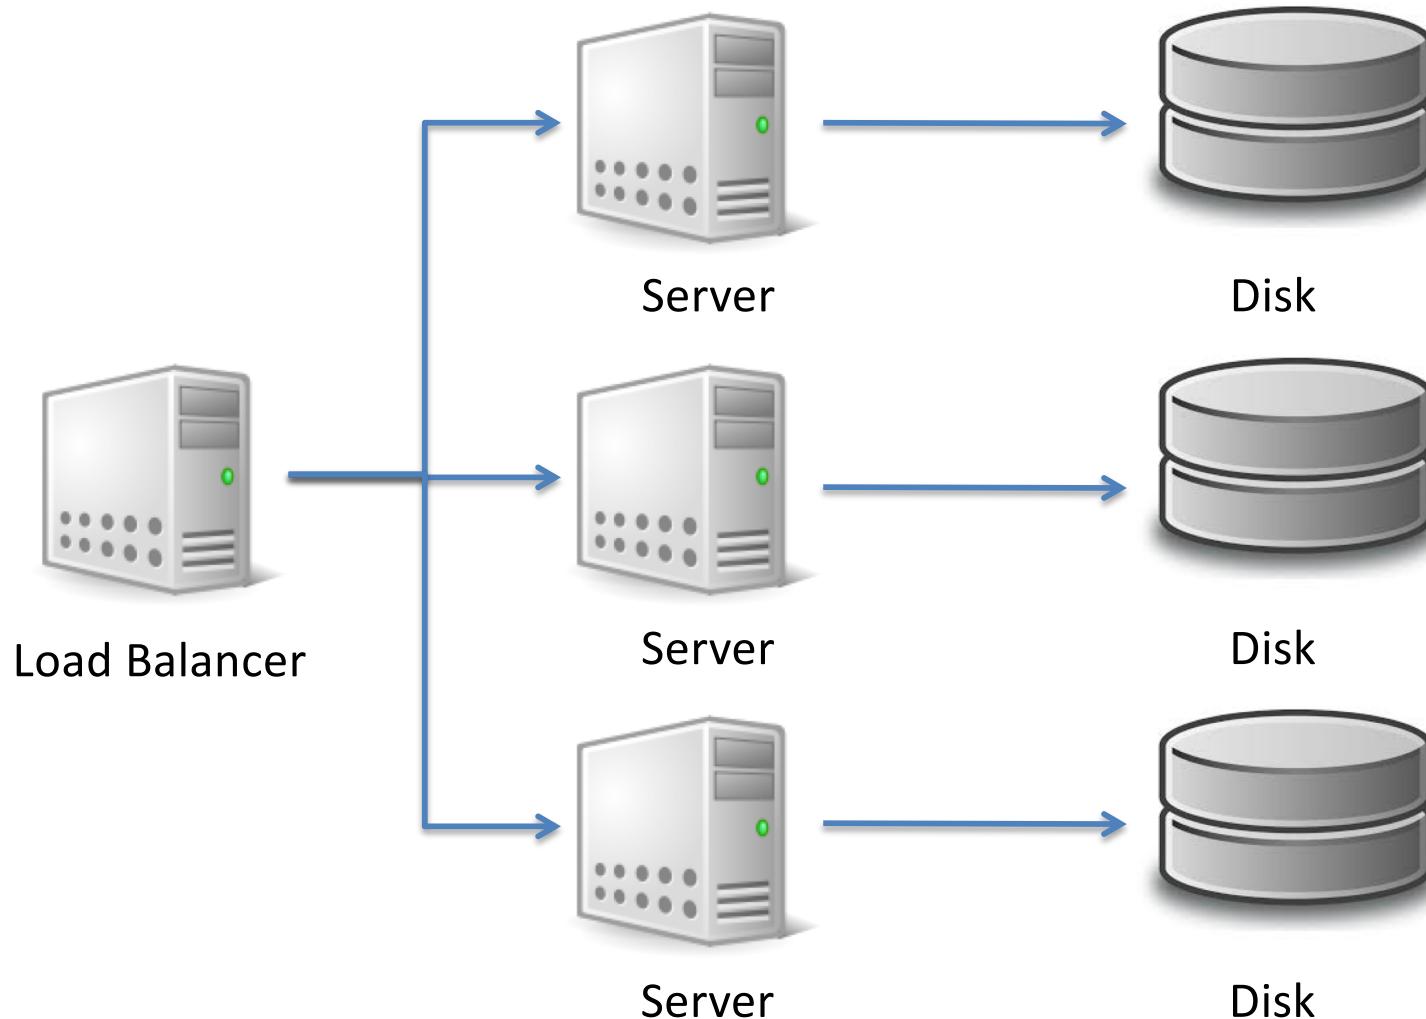

$e > 1$  indicates adding processors  
slows down the system!!!

$$\begin{aligned}\psi &= 2 \\ p &= 10 \\ e &= 4/9\end{aligned}$$

$$\begin{aligned}\psi &= 0.5 \\ p &= 10 \\ e &= 19/9\end{aligned}$$

# Shared Nothing Architecture

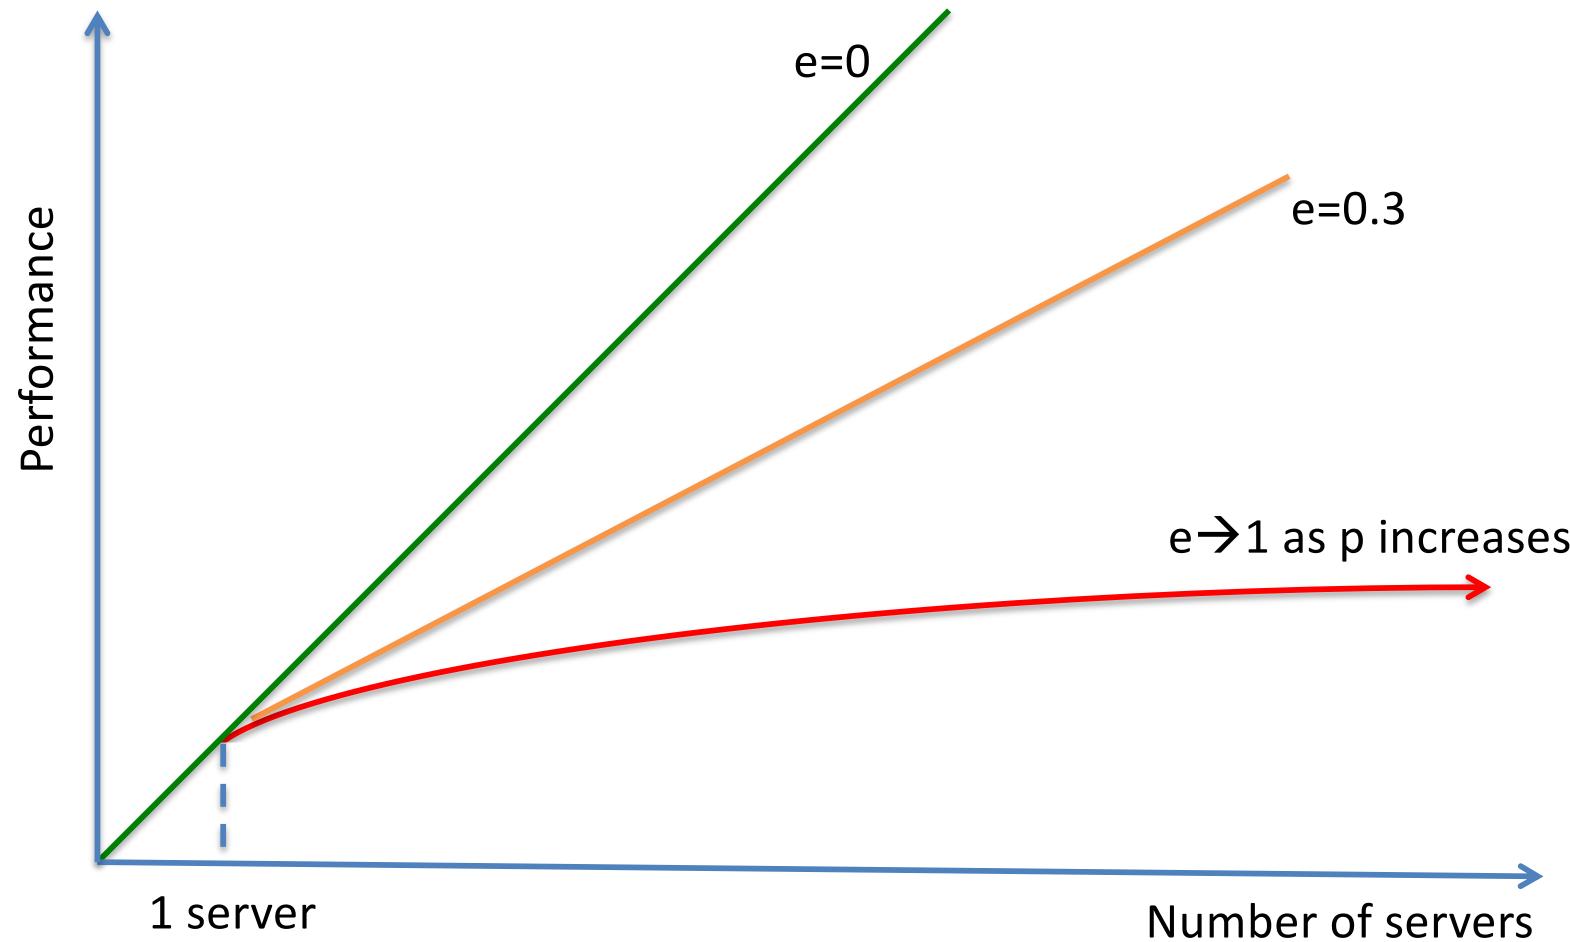

# Shared Nothing Architecture

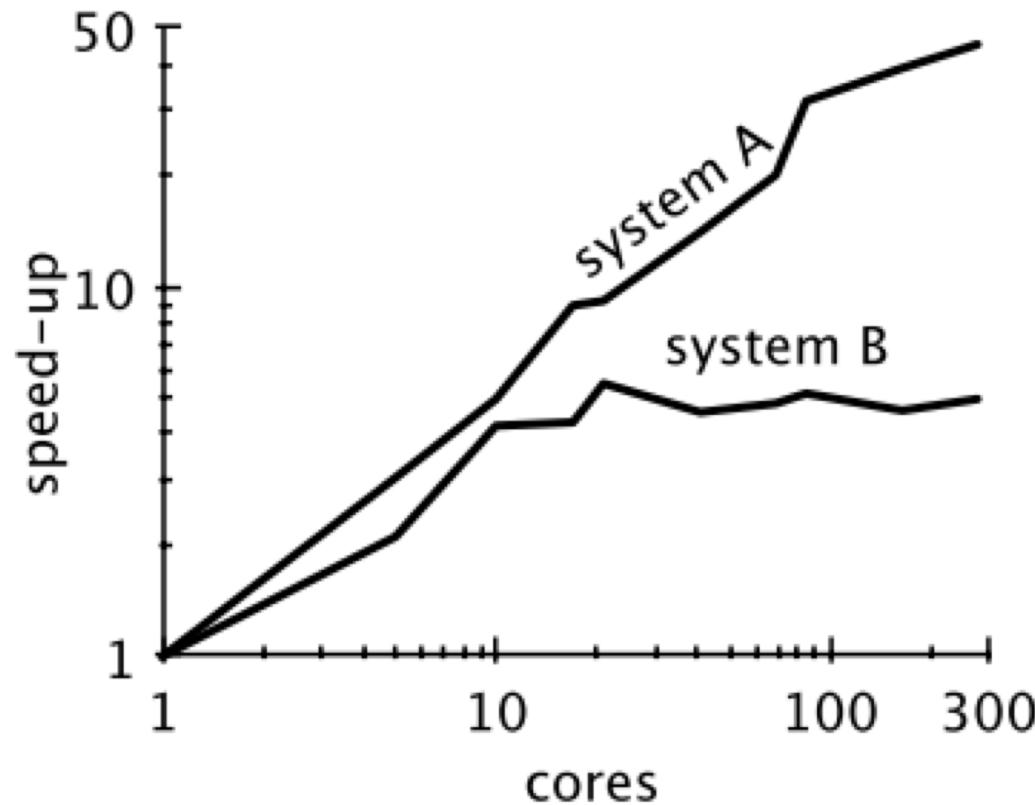

- Implies there is no serial part to the computation
- Karp-Flatt Metric of 0
  - Assuming 100% efficient load balancing
- In practice, this is difficult!

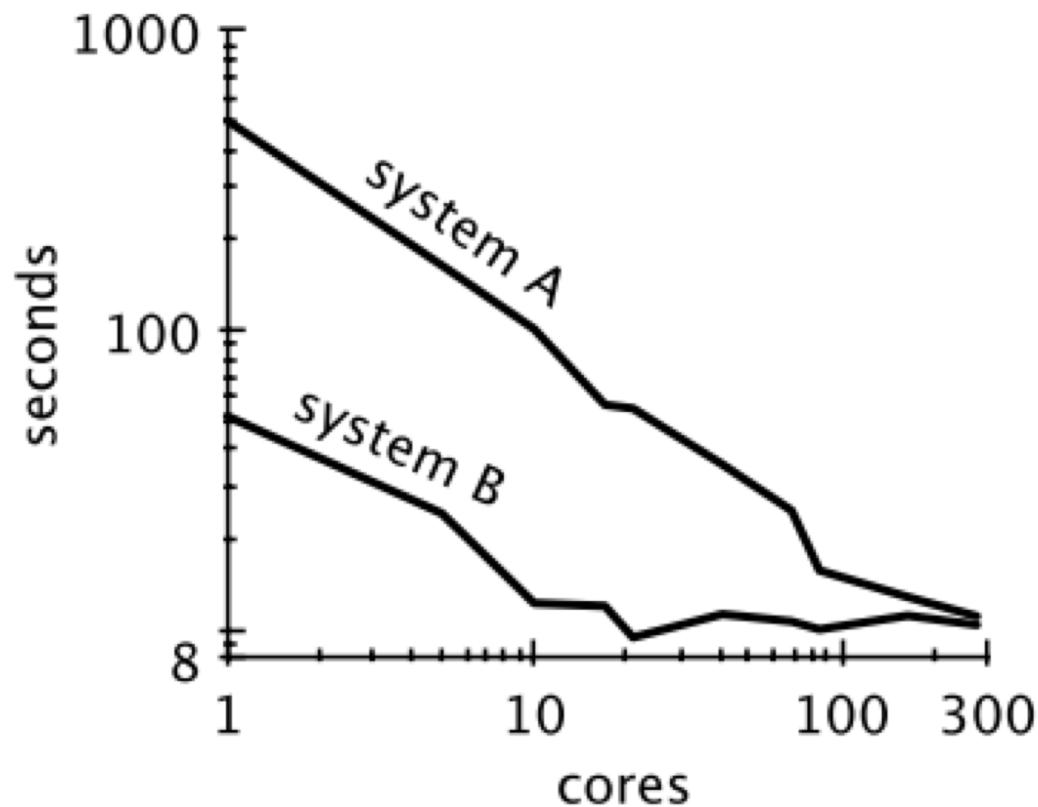

# Karp-Flatt metric

# Warning

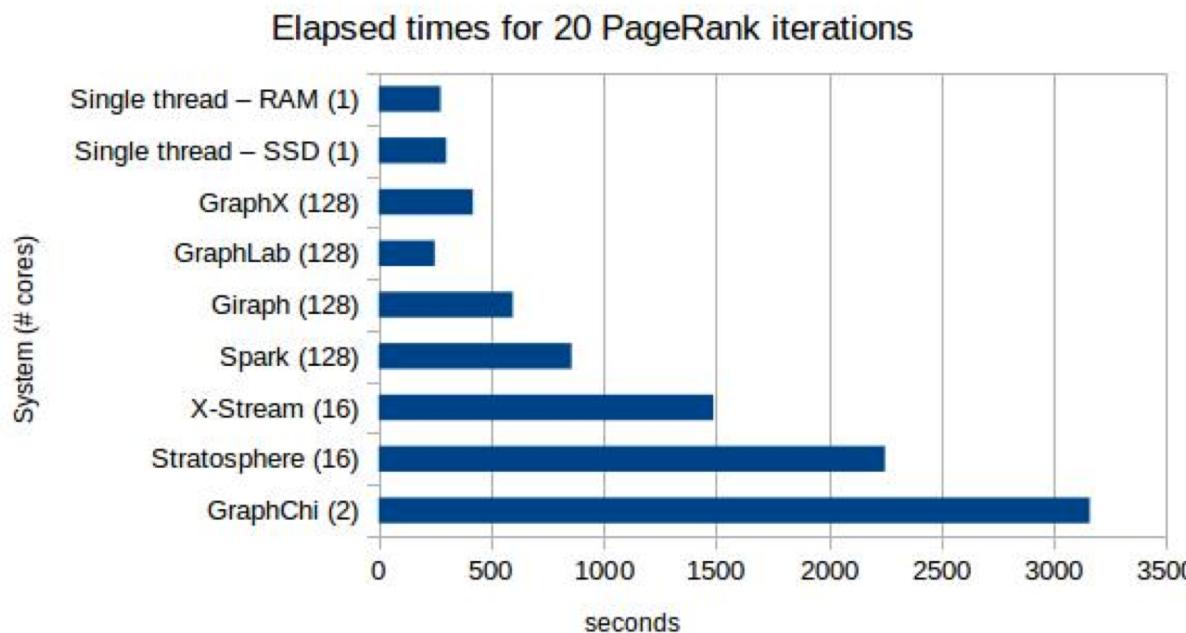

# Same systems, new diagram

# Scalability at what COST

- COST = Configuration that Outperforms a Single Thread
  - <http://www.frankmcsherry.org/assets/COST.pdf>
  - <http://www.frankmcsherry.org/graph/scalability/cost/2015/01/15/COST.html>

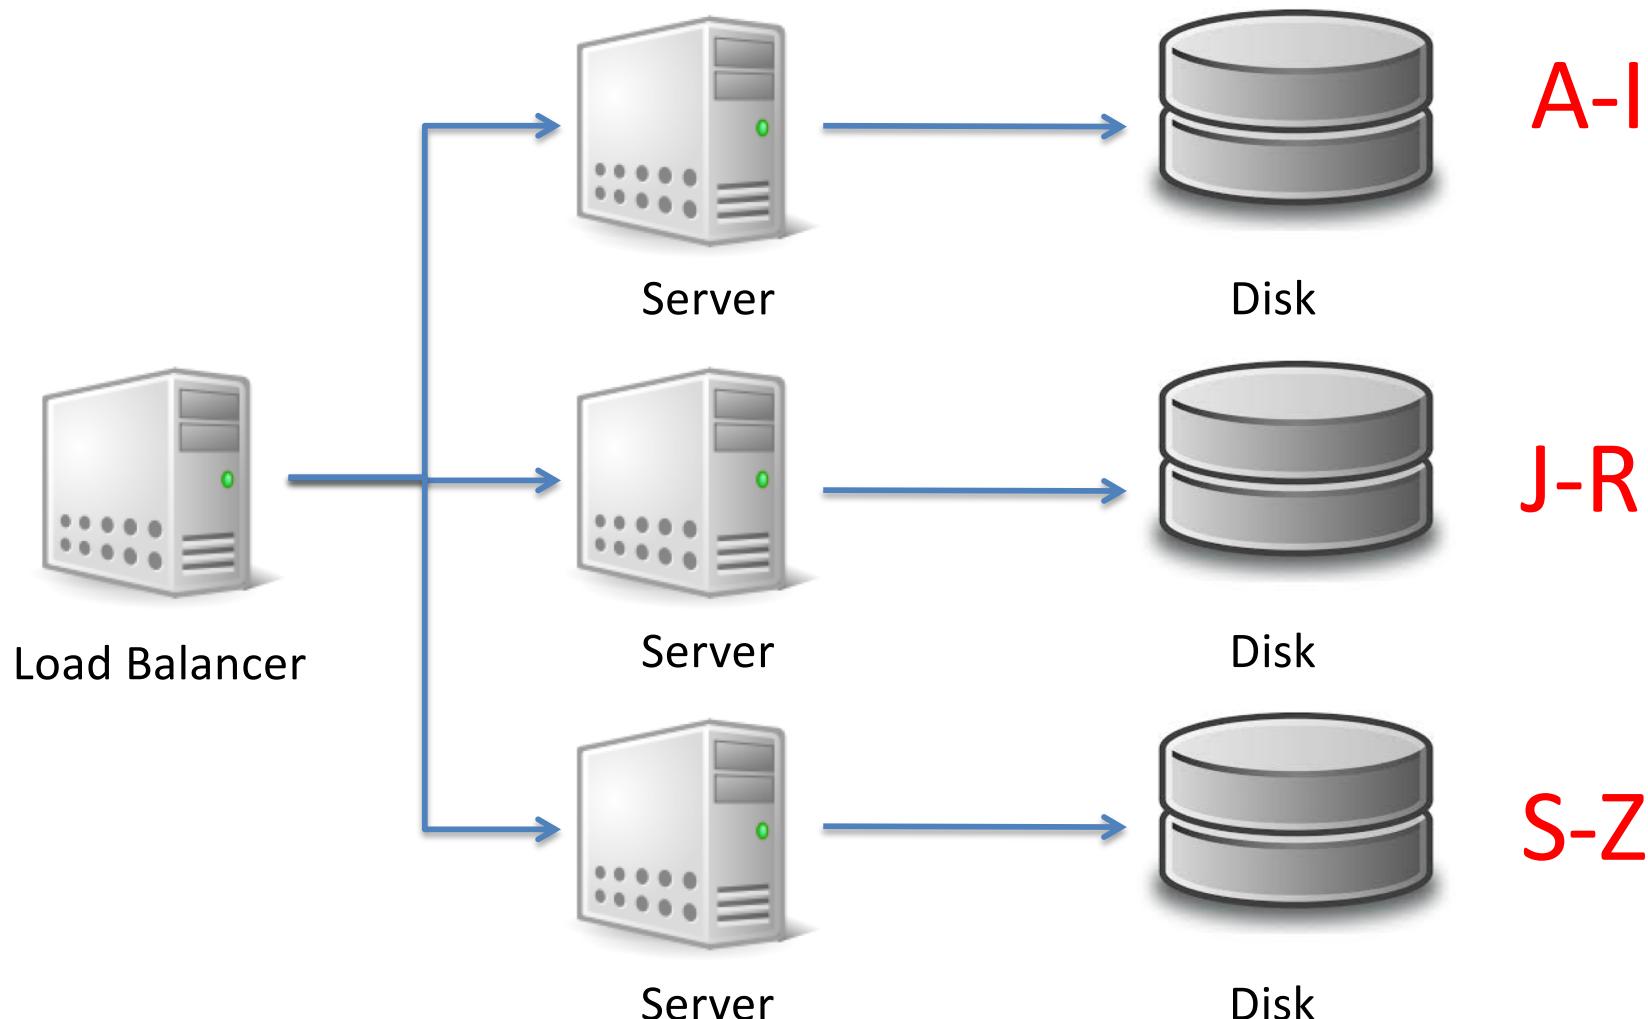

# Data partitioning

- Data centres scale horizontally not vertically
- Partition data horizontally
  - different rows of a table stored on different nodes

# Data Partitioning / Sharding

# Problems with Sharding

- Imbalance
  - Fewer S-Z's than A-I's
- Failover
  - what happens if one of the servers crashes?
- Adding new servers requires a re-balance
  - Is this automatic or manual?!

# Data Validity

- What properties should database transactions have to ensure validity in the case of power failures or errors?
- Transferring money from one bank account to another
  - what if there is a power outage mid-transaction?
- How does this work at scale? In data centres?

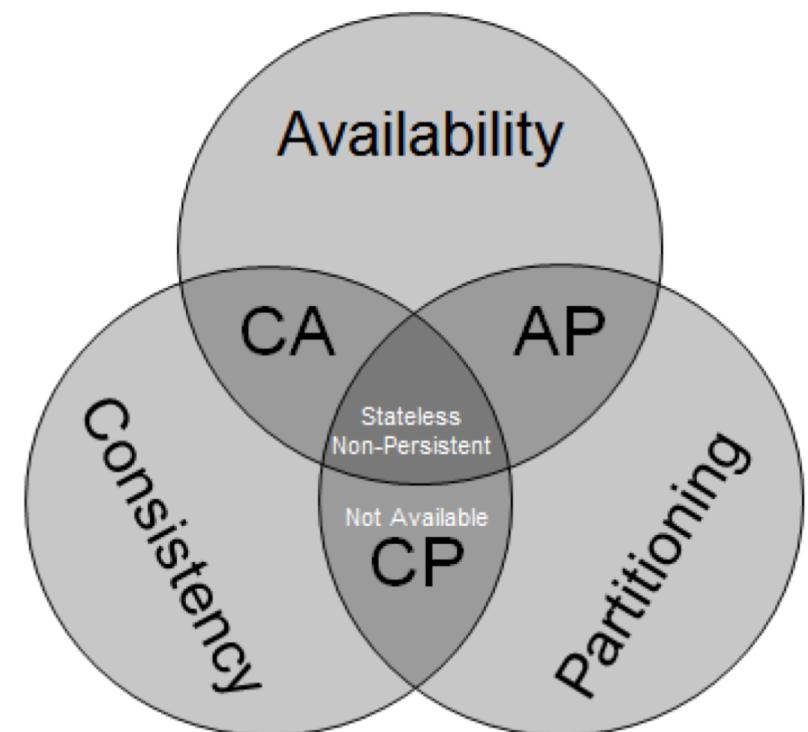

# ACID

- *atomicity*
  - all-or-nothing
- *consistency*
  - integrity-preserving: invariants satisfied
- *isolation*
  - concurrent execution is the same as sequential execution
  - hidden intermediate results
  - multi-user behaviour consistent with single-user mode
- *durability*
  - permanent committed results

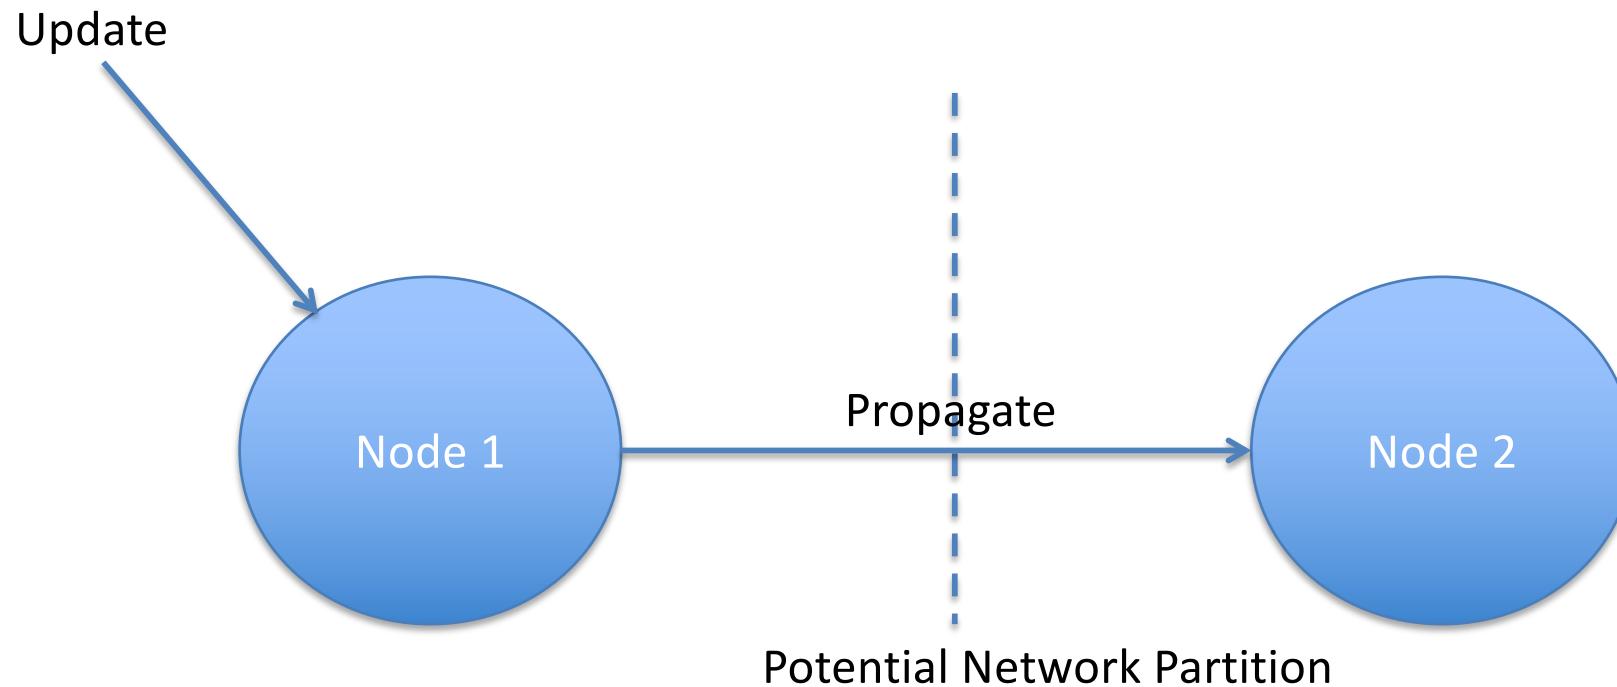

# CAP Theorem

- Originally proposed by Eric Brewer
  - Proved in 2002 by Gilbert and Lynch
- You can have 2 out of three:
  - Consistent
    - every read receives the most recent write or an error
  - Available
    - every request gets a (non-error) response
  - Partition tolerance
    - system continues to operate despite an arbitrary number of messages dropped (or delayed) between nodes

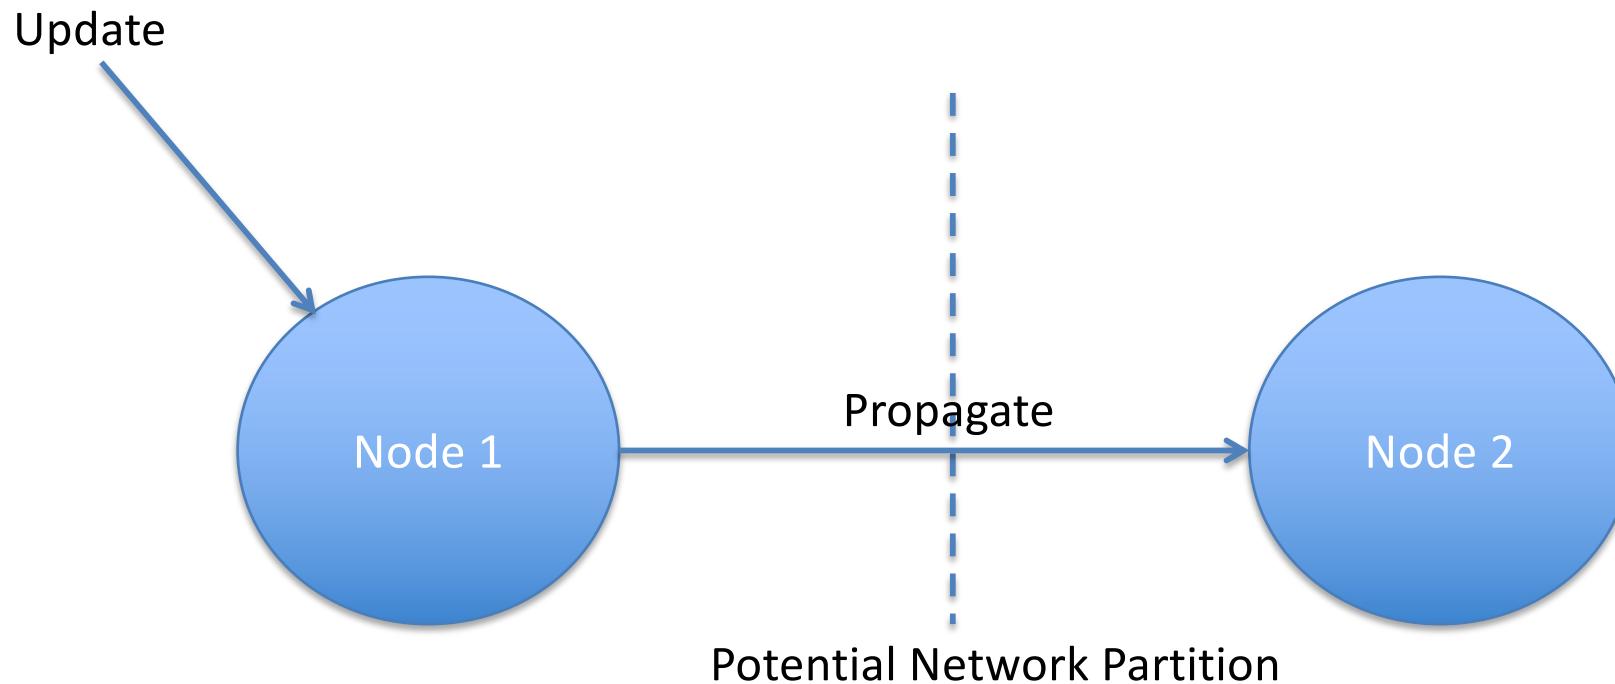

# Imagine two nodes

Network partition occurs if the network switch device between two subnets fails.

# Imagine two nodes

If there is a partition, then you can **either** update one node (give up on C), **or** make one node unavailable (give up on A).

If you want C and A you can't allow a Partition.

# CAP options

- CA
  - Traditional databases
  - Cannot be scaled multi-datacentre or work in cases of high-latency
- AP
  - Multi-master NoSQL databases
    - Dynamo, Cassandra, CouchDB
    - Not consistent but work across datacentres in a highly available model
- CP
  - Not a good idea, as not available!

# CAP Theorem

- The proof requires some complex definitions of C, A and P
- I recommend reading Brewer's update:
  - <http://www.infoq.com/articles/cap-twelve-years-later-how-the-rules-have-changed>
  - “The 2 of 3 formulation was always misleading”
  - “CAP prohibits only a tiny part of the design space”

# In real life

- Network partitions are rare
- So we can implement a strategy:
  - Detect a partition
  - Enter “partition mode”
  - Carry on with inconsistency
  - Recover when partition vanishes
- Known as “eventually consistent”

# What does recovery mean?

- Depends on your database and requirements
  - E.g. Amazon's shopping cart is made consistent by creating the union of the inconsistent carts
  - Deleted items may re-appear
- Another option is to forbid certain operations during partition mode
  - To make it easier to recover consistency
- A simplistic approach would be to go read-only

# What does that mean in real-life?

- Databases like Cassandra let you “tune” consistency and availability
  - Define the quorum you need for a response
  - Trades off latency vs consistency
    - Choose an “easy quorum” for guaranteed low latency
    - Choose a “hard quorum” for higher potential latency

# Cassandra Quorum Levels (Write)

## Write Consistency Levels

Level	Description	Usage
ALL	A write must be written to the <a href="#">commit log and memtable</a> on all replica nodes in the cluster for that <a href="#">partition</a> .	Provides the highest consistency and the lowest availability of any other level.
EACH_QUORUM	Strong consistency. A write must be written to the <a href="#">commit log and memtable</a> on a quorum of replica nodes in <i>all</i> <a href="#">data centers</a> .	Used in multiple data center clusters to strictly maintain consistency at the same level in each data center. For example, choose this level if you want a read to fail when a data center is down and the QUORUM cannot be reached on that data center.
QUORUM	A write must be written to the <a href="#">commit log and memtable</a> on a quorum of replica nodes.	Provides strong consistency if you can tolerate some level of failure.
LOCAL_QUORUM	Strong consistency. A write must be written to the <a href="#">commit log and memtable</a> on a quorum of replica nodes in the same data center as the <a href="#">coordinator node</a> . Avoids latency of inter-data center communication.	Used in multiple data center clusters with a rack-aware replica placement strategy, such as <a href="#">NetworkTopologyStrategy</a> , and a properly configured snitch. Use to maintain consistency locally (within the single data center). Can be used with <a href="#">SimpleStrategy</a> .
ONE	A write must be written to the <a href="#">commit log and memtable</a> of at least one replica node.	Satisfies the needs of most users because consistency requirements are not stringent.
TWO	A write must be written to the <a href="#">commit log and memtable</a> of at least two replica nodes.	Similar to ONE.
THREE	A write must be written to the <a href="#">commit log and memtable</a> of at least three replica nodes.	Similar to TWO.
LOCAL_ONE	A write must be sent to, and successfully acknowledged by, at least one replica node in the local data center.	In a multiple data center clusters, a consistency level of ONE is often desirable, but cross-DC traffic is not. LOCAL_ONE accomplishes this. For security and quality reasons, you can use this consistency level in an offline datacenter to prevent automatic connection to online nodes in other data centers if an offline node goes down.
ANY	A write must be written to at least one node. If all replica nodes for the given partition key are down, the write can still succeed after a <a href="#">hinted handoff</a> has been written. If all replica nodes are down at write time, an ANY write is not readable until the replica nodes for that partition have recovered.	Provides low latency and a guarantee that a write never fails. Delivers the lowest consistency and highest availability.
SERIAL	Achieves <a href="#">linearizable consistency</a> for lightweight transactions by preventing unconditional updates.	You cannot configure this level as a normal consistency level, configured at the driver level using the consistency level field. You configure this level using the serial consistency field as part of the <a href="#">native protocol operation</a> . See failure scenarios.
LOCAL_SERIAL	Same as SERIAL but confined to the data center. A write must be written conditionally to the <a href="#">commit log and memtable</a> on a quorum of replica nodes in the same data center.	Same as SERIAL. Used for disaster recovery. See failure scenarios.

# Summary

- We have looked at the challenges to scaling on multiple servers
  - Serial vs Parallel
  - Fixed data vs growing
  - CAP
  - Eventually Consistent
